

## 3 Introduction

### Parallel Computing

A **parallel computer** is a collection of processors **usually of the same type**, interconnected to allow coordination and exchange of data.

The processors are primarily used to **jointly** solve a given problem.

### Distributed Systems

A set of possibly many **different types** of processors are distributed over a larger geographic area.

Processors do not work on a single problem.

Some processors may act in a malicious way.

## How do we evaluate sequential algorithms?

- ▶ time efficiency
- ▶ space utilization
- ▶ energy consumption
- ▶ programmability
- ▶ ...

Asymptotic bounds (e.g., for running time) often give a good indication on the algorithms performance on a **wide variety of machines**.

# Cost measures

## How do we evaluate parallel algorithms?

- ▶ time efficiency
- ▶ space utilization
- ▶ energy consumption
- ▶ programmability
- ▶ communication requirement
- ▶ ...

## Problems

- ▶ performance (e.g. runtime) depends on problem size  $n$  **and** on number of processors  $p$
- ▶ statements usually only hold for restricted types of parallel machine as parallel computers may have vastly different characteristics (in particular w.r.t. communication)

# Speedup

Suppose a problem  $P$  has **sequential complexity**  $T^*(n)$ , i.e., there is no algorithm that solves  $P$  in time  $o(T^*(n))$ .

## Definition 1

The **speedup**  $S_p(n)$  of a parallel algorithm  $A$  that requires time  $T_p(n)$  for solving  $P$  with  $p$  processors is defined as

$$S_p(n) = \frac{T^*(n)}{T_p(n)} .$$

Clearly,  $S_p(n) \leq p$ . **Goal:** obtain  $S_p(n) \approx p$ .

It is common to replace  $T^*(n)$  by the time bound of the best **known** sequential algorithm for  $P$ !

# Efficiency

## Definition 2

The **efficiency** of a parallel algorithm  $A$  that requires time  $T_p(n)$  when using  $p$  processors on a problem of size  $n$  is

$$E_p(n) = \frac{T_1(n)}{pT_p(n)} .$$

$E_p(n) \approx 1$  indicates that the algorithm is running roughly  $p$  times faster with  $p$  processors than with one processor.

Note that  $E_p(n) \leq \frac{T_1(n)}{pT_\infty(n)}$ . Hence, the efficiency goes down rapidly if  $p \geq T_1(n)/T_\infty(n)$ .

**Disadvantage: cost-measure does not relate to the optimum sequential algorithm.**

# Parallel Models — Requirements

## **Simplicity**

A model should allow to easily analyze various performance measures (speed, communication, memory utilization etc.).

Results should be as hardware-independent as possible.

## **Implementability**

Parallel algorithms developed in a model should be easily implementable on a parallel machine.

Theoretical analysis should carry over and give meaningful performance estimates.

**A real satisfactory model does not exist!**

## DAG model — computation graph

- ▶ nodes represent operations (single instructions or larger blocks)
- ▶ edges represent dependencies (precedence constraints)
- ▶ closely related to circuits; however there exist many different variants
- ▶ branching instructions cannot be modelled
- ▶ completely hardware independent
- ▶ scheduling is not defined

**Often used for automatically parallelizing numerical computations.**

## Example: Addition

Here, vertices without incoming edges correspond to input data.  
The graph can be viewed as a **data flow graph**.

# DAG model — computation graph

The DAG itself is not a complete algorithm. A **scheduling** implements the algorithm on a parallel machine, by assigning a time-step  $t_v$  and a processor  $p_v$  to every node.

## Definition 3

A **scheduling** of a DAG  $G = (V, E)$  on  $p$  processors is an assignment of pairs  $(t_v, p_v)$  to every **internal** node  $v \in V$ , s.t.,

- ▶  $p_v \in \{1, \dots, p\}; t_v \in \{1, \dots, T\}$
- ▶  $t_u = t_v \Rightarrow p_u \neq p_v$
- ▶  $(u, v) \in E \Rightarrow t_v \geq t_u + 1$

where a non-internal node  $x$  (an input node) has  $t_x = 0$ .

$T$  is the **length** of the schedule.

## DAG model — computation graph

The **parallel complexity** of a DAG is defined as

$$T_p(n) = \min_{\text{schedule } S} \{T(S)\} .$$

$T_1(n)$ : #internal nodes in DAG

$T_\infty(n)$ : diameter of DAG

Clearly,

$$T_p(n) \geq T_\infty(n)$$

$$T_p(n) \geq T_1(n)/p$$

### Lemma 4

*A schedule with length  $\mathcal{O}(T_1(n)/p + T_\infty(n))$  can be found easily.*

### Lemma 5

*Finding an optimal schedule is in general NP-complete.*

Note that the DAG model as defined is a **non-uniform** model of computation.

In principle, there could be a different DAG for every input size  $n$ .

An algorithm (e.g. for a RAM) must work for every input size and must be of finite description length.

Hence, specifying a different DAG for every  $n$  has more expressive power.

Also, this is not really a complete model, as the operations allowed in a DAG node are not clearly defined.

# PRAM Model

All processors are **synchronized**.

In every round a processor can:

- ▶ read a register from global memory into local memory
- ▶ do a local computation à la RAM
- ▶ write a local register into global memory

# PRAM Model

Every processor executes the same program.

However, the program has access to two special variables:

- ▶  $p$ : total number of processors
- ▶  $id \in \{1, \dots, p\}$ : the id of the current processor

The following (stupid) program copies the content of the global register  $x[1]$  to registers  $x[2] \dots x[p]$ .

## Algorithm 1 copy

```
1: if  $id = 1$  then  $round \leftarrow 1$   
2: while  $round \leq p$  and  $id = round$  do  
3:    $x[id + 1] \leftarrow x[id]$   
4:    $round \leftarrow round + 1$ 
```

## PRAM Model

- ▶ processors can effectively execute different code because of branching according to  $id$
- ▶ however, not arbitrarily; still **uniform model of computation**

Often it is easier to explicitly define which parts of a program are executed in parallel:

### Algorithm 2 sum

```
1: // computes sum of  $x[1] \dots x[p]$ 
2: // red part is executed only by processor 1
3:  $r \leftarrow 1$ 
4: while  $2^r \leq p$  do
5:     for  $id \bmod 2^r = 1$  par do
6:         // only executed by processors whose  $id$  matches
7:              $x[id] = x[id] + x[id + 2^{r-1}]$ 
8:      $r \leftarrow r + 1$ 
9: return  $x[1]$ 
```

# Different Types of PRAMs

## Simultaneous Access to Shared Memory:

- ▶ EREW PRAM:  
simultaneous access is not allowed
- ▶ CREW PRAM:  
concurrent read accesses to the same location are allowed;  
write accesses have to be exclusive
- ▶ CRCW PRAM:  
concurrent read and write accesses allowed
  - ▶ common CRCW PRAM  
all processors writing to  $x[i]$  must write same value
  - ▶ arbitrary CRCW PRAM  
values may be different; an arbitrary processor succeeds
  - ▶ priority CRCW PRAM  
values may be different; processor with smallest id succeeds

### Algorithm 3 sum

```
1: // computes sum of  $x[1] \dots x[p]$ 
2:  $r \leftarrow 1$ 
3: while  $2^r \leq p$  do
4:   for  $id \bmod 2^r = 1$  pardo
5:      $x[id] = x[id] + x[id + 2^{r-1}]$ 
6:    $r \leftarrow r + 1$ 
7: return  $x[1]$ 
```

The above is an EREW PRAM algorithm.

On a CREW PRAM we could replace Line 4 by  
**for**  $1 \leq id \leq p$  **pardo**

## PRAM Model — remarks

- ▶ similar to a RAM we either need to restrict the size of values that can be stored in registers, or we need to have a non-uniform cost model for doing a register manipulation (cost for manipulating  $x[i]$  is proportional to the bit-length of the largest number that is ever being stored in  $x[i]$ )
  - ▶ in this lecture: uniform cost model but we are not exploiting the model
- ▶ **global shared memory** is very unrealistic in practise as uniform access to all memory locations does not exist
- ▶ **global synchronziation** is very unrealistic; in real parallel machines a global synchronization is very costly
- ▶ model is good for understanding basic parallel mechanisms/techniques but **not** for algorithm development
- ▶ model is good for **lower bounds**

# Network of Workstations — NOWs

- ▶ interconnection network represented by a graph  $G = (V, E)$
- ▶ each  $v \in V$  represents a processor
- ▶ an edge  $\{u, v\} \in E$  represents a two-way communication link between processors  $u$  and  $v$
- ▶ network is **asynchronous**
- ▶ all coordination/communication has to be done by explicit **message passing**

# Typical Topologies

## Network of Workstations — NOWs

Computing the sum on a  $d$ -dimensional hypercube. Note that  $x[0] \dots x[2^d - 1]$  are stored at the individual nodes.

Processors are numbered consecutively starting from 0

### Algorithm 4 sum

```
1: // computes sum of  $x[0] \dots x[2^d - 1]$ 
2:  $r \leftarrow 1$ 
3: while  $2^r \leq 2^d$  do //  $p = 2^d$ 
4:     if  $id \bmod 2^r = 0$  then
5:          $temp \leftarrow receive(id + 2^{r-1})$ 
6:          $x[id] = x[id] + temp$ 
7:     if  $id \bmod 2^r = 2^{r-1}$  then
8:          $send(x[id], id - 2^{r-1})$ 
9:      $r \leftarrow r + 1$ 
10: if  $id = 0$  then return  $x[id]$ 
```

## Remarks

- ▶ One has to ensure that at any point in time there is at most one active communication along a link
- ▶ There also exist synchronized versions of the model, where in every round each link can be used once for communication
- ▶ In particular the asynchronous model is quite realistic
- ▶ Difficult to develop and analyze algorithms as a lot of low level communication has to be dealt with
- ▶ Results only hold for one specific topology and cannot be generalized easily

# Performance of PRAM algorithms

Suppose that we can solve an instance of a problem with size  $n$  with  $P(n)$  processors and time  $T(n)$ .

We call  $C(n) = T(n) \cdot P(n)$  the **time-processor** product or the **cost** of the algorithm.

The following statements are equivalent

- ▶  $P(n)$  processors and time  $\mathcal{O}(T(n))$
- ▶  $\mathcal{O}(C(n))$  cost and time  $\mathcal{O}(T(n))$
- ▶  $\mathcal{O}(C(n)/p)$  time for any number  $p \leq P(n)$  processors
- ▶  $\mathcal{O}(C(n)/p + T(n))$  for any number  $p$  of processors

## Performance of PRAM algorithms

Suppose we have a PRAM algorithm that takes time  $T(n)$  and work  $W(n)$ , where work is the total number of operations.

We can **nearly always** obtain a PRAM algorithm that uses time at most

$$\lceil W(n)/p \rceil + T(n)$$

parallel steps on  $p$  processors.

**Idea:**

- ▶  $W_i(n)$  denotes operations in parallel step  $i$ ,  $1 \leq i \leq T(n)$
- ▶ simulate each step in  $\lceil W_i(n)/p \rceil$  parallel steps
- ▶ then we have

$$\sum_i \lceil W_i(n)/p \rceil \leq \sum_i (\lfloor W_i(n)/p \rfloor + 1) \leq \lfloor W(n)/p \rfloor + T(n)$$

# Performance of PRAM algorithms

Why nearly always?

We need to assign processors to operations.

- ▶ every processor  $p_i$  needs to know whether it should be active
- ▶ in case it is active it needs to know which operations to perform

**design algorithms for an arbitrary number of processors;  
keep total time and work low**

## Optimal PRAM algorithms

Suppose the optimal sequential running time for a problem is  $T^*(n)$ .

We call a PRAM algorithm for the same problem **work optimal** if its work  $W(n)$  fulfills

$$W(n) = \Theta(T^*(n))$$

If such an algorithm has running time  $T(n)$  it has **speedup**

$$S_p(n) = \Omega\left(\frac{T^*(n)}{T^*(n)/p + T(n)}\right) = \Omega\left(\frac{pT^*(n)}{T^*(n) + pT(n)}\right) = \Omega(p)$$

for  $p = \mathcal{O}(T^*(n)/T(n))$ .

This means by improving the time  $T(n)$ , (while using same work) we improve the range of  $p$ , for which we obtain optimal speedup.

We call an algorithm **worktime (WT) optimal** if  $T(n)$  cannot be asymptotically improved by any **work optimal** algorithm.

## Example

Algorithm for computing the sum has work  $W(n) = \mathcal{O}(n)$ .

optimal

$T(n) = \mathcal{O}(\log n)$ . Hence, we achieve an optimal speedup for  $p = \mathcal{O}(n / \log n)$ .

One can show that any CREW PRAM requires  $\Omega(\log n)$  time to compute the sum.

# Communication Cost

When we differentiate between **local** and **global** memory we can analyze communication cost.

We define the **communication cost** of a PRAM algorithm as the worst-case traffic between the local memory of a processor and the global shared memory.

**Important criterion as communication is usually a major bottleneck.**

# Communication Cost

## Algorithm 5 MatrixMult( $A, B, n$ )

```
1: Input:  $n \times n$  matrix  $A$  and  $B$ ;  $n = 2^k$ 
2: Output:  $C = AB$ 
3: for  $1 \leq i, j, \ell \leq n$  pardo
4:      $X[i, j, \ell] \leftarrow A[i, \ell] \cdot B[\ell, j]$ 
5: for  $r \leftarrow 1$  to  $\log n$ 
6:     for  $1 \leq i, j \leq n$ ;  $\ell \bmod 2^r = 1$  pardo
7:          $X[i, j, \ell] \leftarrow X[i, j, \ell] + X[i, j, \ell + 2^{r-1}]$ 
8:  $C[i, j] \leftarrow X[i, j, \ell]$ 
```

On  $n^3$  processors this algorithm runs in time  $\mathcal{O}(\log n)$ .  
It uses  $n^3$  multiplications and  $\mathcal{O}(n^3)$  additions.

What happens if we have  $n$  processors?

### Phase 1

$p_i$  computes  $X[i, j, \ell] = A[i, \ell] \cdot B[\ell, j]$  for all  $1 \leq j, \ell \leq n$   
 $n^2$  time;  $n^2$  communication for every processor

### Phase 2 (round $r$ )

$p_i$  updates  $X[i, j, \ell]$  for all  $1 \leq j \leq n; 1 \leq \ell \bmod 2^r = 1$   
 $n \cdot n/2^r$  time; no communication

### Phase 3

$p_i$  writes  $i$ -th row into  $C[i, j]$ 's.  
 $n$  time;  $n$  communication

## Alternative Algorithm

Split matrix into blocks of size  $n^{2/3} \times n^{2/3}$ .

$A_{1,1}$	$A_{1,2}$	$A_{1,3}$	$A_{1,4}$
$A_{2,1}$	$A_{2,2}$	$A_{2,3}$	$A_{2,4}$
$A_{3,1}$	$A_{3,2}$	$A_{3,3}$	$A_{3,4}$
$A_{4,1}$	$A_{4,2}$	$A_{4,3}$	$A_{4,4}$

 $\cdot$ 

$B_{1,1}$	$B_{1,2}$	$B_{1,3}$	$B_{1,4}$
$B_{2,1}$	$B_{2,2}$	$B_{2,3}$	$B_{2,4}$
$B_{3,1}$	$B_{3,2}$	$B_{3,3}$	$B_{3,4}$
$B_{4,1}$	$B_{4,2}$	$B_{4,3}$	$B_{4,4}$

 $=$ 

$C_{1,1}$	$C_{1,2}$	$C_{1,3}$	$C_{1,4}$
$C_{2,1}$	$C_{2,2}$	$C_{2,3}$	$C_{2,4}$
$C_{3,1}$	$C_{3,2}$	$C_{3,3}$	$C_{3,4}$
$C_{4,1}$	$C_{4,2}$	$C_{4,3}$	$C_{4,4}$

Note that  $C_{i,j} = \sum_{\ell} A_{i,\ell} B_{\ell,j}$ .

Now we have the same problem as before but  $n' = n^{1/3}$  and a single multiplication costs time  $\mathcal{O}((n^{2/3})^3) = \mathcal{O}(n^2)$ . An addition costs  $n^{4/3}$ .

work for multiplications:  $\mathcal{O}(n^2 \cdot (n')^3) = \mathcal{O}(n^3)$

work for additions:  $\mathcal{O}(n^{4/3} \cdot (n')^3) = \mathcal{O}(n^3)$

time:  $\mathcal{O}(n^2) + \log n' \cdot \mathcal{O}(n^{4/3}) = \mathcal{O}(n^2)$

# Alternative Algorithm

The communication cost is only  $\mathcal{O}(n^{4/3} \log n')$  as a processor in the original problem touches at most  $\log n$  entries of the matrix.

Each entry has size  $\mathcal{O}(n^{4/3})$ .

The algorithm exhibits less parallelism but still has optimum work/runtime for just  $n$  processors.

**much, much better in practise**
